**SPECIFICATION**

TO ALL WHOM IT MAY CONCERN:

WE, John P. Snyder, a resident of Edina, Minnesota, and John M. Larson, a resident of Northfield, Minnesota, and both Citizens of the United States of America, have invented certain new and useful improvements in an

**TRANSISTOR HAVING HIGH DIELECTRIC CONSTANT GATE  
INSULATING LAYER AND SOURCE AND DRAIN FORMING SCHOTTKY  
CONTACT WITH SUBSTRATE**

of which the following is a specification.

However, in practical applications, the drive current in the “on” state is not ideal because of parasitic impedances associated with other parts of the semiconductor device 100. For example, the source and drain regions have a finite impedance, resulting in a parasitic impedance which adds to the resistance of the channel region. Also, in practical applications, there is a certain finite amount of leakage current when the semiconductor device is “off.”

[005] In prior art current regulating devices, the drive current is linearly proportional to the dielectric constant  $K$  of the insulating layer 150, and linearly inversely proportional to the thickness  $T_{ins}$  of the insulating layer 150. The drive current  $I_D$  is approximated by the relationship:

[006] 
$$I_D \sim K/T_{ins}$$

[007] where  $K$  is the dielectric constant of the insulating layer and  $T_{ins}$  is the thickness of the insulating layer.

[008] One consideration in the design of current regulating devices is reducing the amount of power required to achieve a desired drive current. One way to reduce power consumption is by using a metal source and drain and a simple, uniformly implanted channel dopant profile, as described in copending U.S. Patent Applications 09/465,357, filed on December 16, 1999, entitled “METHOD OF MANUFACTURING A SHORT-CHANNEL FET WITH SCHOTTKY BARRIER SOURCE AND DRAIN CONTACTS,” and 09/777,536, filed on February 6, 2001, entitled “MOSFET DEVICE AND MANUFACTURING METHOD,” the contents of which are hereby incorporated by reference.

[009] Another consideration in the design of current regulating devices is the manufacturability. One way to improve the manufacturability of current regulating devices having gate insulators with high dielectric constant materials is to form the source and drain electrodes using a low temperature process such as that used for formation of Schottky or Schottky-like source and drain electrodes, as described in U.S. Provisional Patent Application 60/381,320, filed on May 16,

2002, entitled "LOW TEMPERATURE SOURCE AND DRAIN FORMATION PROCESS STEPS FOR THE MANUFACTURE OF MOSFET DEVICES," the contents of which are hereby incorporated by reference.

5       **[010]**       There is a need in the art for a device for regulating the flow of electric current, which exhibits an improved drive current in the "on" state. There is a further need in the art for a method of manufacturing such a device at reduced temperatures.

#### BRIEF SUMMARY OF THE INVENTION

10       **[011]**       By using the invention disclosed herein the drive current characteristics can be improved, resulting in a non-linear relationship between the drive current  $I_D$  and both the dielectric constant ( $K$ ) of the insulating layer and the thickness of the insulating layer  $T_{ins}$ . The resulting relationship results in current regulating devices that are more sensitive to variations in  $K$  and  $T_{ins}$  compared to the prior art. Furthermore, by using the invention disclosed herein, the manufacturability of new gate insulator materials is improved substantially.

15       **[012]**       In one aspect, the invention provides a method for manufacturing a device for regulating the flow of electrical current. The method includes the steps of providing for a semiconductor substrate; providing for an electrically insulating layer in contact with the semiconductor substrate, the insulating layer having a dielectric constant greater than 4.0; providing for a gate electrode in contact with at least a portion of the insulating layer; and providing a source electrode and a drain electrode in contact with the semiconductor substrate and proximal to the gate electrode wherein at least one of the source electrode and the drain electrode forms a Schottky contact or Schottky-like region with the semiconductor substrate. In one aspect, the device for regulating the flow of electrical current may be a Metal Oxide Semiconductor Field Effect Transistor (MOSFET) device. In another aspect, the dielectric constant may be greater than 7.6 or greater than 15.

**[013]** In another aspect, the source and drain electrodes may be formed from a member of the group consisting of: platinum silicide, palladium silicide and iridium silicide. In another aspect, the source and drain electrodes may be formed from a member of the group consisting of the rare earth silicides. In another aspect, the insulating layer may be formed from a member of the group consisting of the metal oxides. In another aspect, the Schottky contact or Schottky-like region may be at least in areas adjacent to the channel. In another aspect, an entire interface between at least one of the source and the drain electrodes and the semiconductor substrate may form a Schottky contact or Schottky-like region with the semiconductor substrate. In another aspect, the channel region may be doped.

**[014]** In another aspect, the invention provides a method for manufacturing a device for regulating the flow of electrical current. The method includes the steps of providing for a semiconductor substrate; providing for an electrically insulating layer in contact with the semiconductor substrate, the insulating layer having a dielectric constant greater than 4.0; providing for a gate electrode located in contact with at least a portion of the insulating layer; exposing the semiconductor substrate on one or more areas proximal to the gate electrode; providing for a thin film of metal on at least a portion of the exposed semiconductor substrate; and reacting the metal with the exposed semiconductor substrate such that a Schottky or Schottky-like source electrode and a drain electrode are formed on the semiconductor substrate. In one aspect, the device for regulating the flow of electrical current may be a MOSFET device. In another aspect, the dielectric constant may be greater than 7.6 or greater than 15.

**[015]** In another aspect, the gate electrode may be provided by the steps of depositing a thin conducting film on the insulating layer; patterning and etching the conducting film to form a gate electrode; and forming one or more thin insulating layers on one or more sidewalls of the gate electrode. In another aspect, the method may include the step of removing metal not reacted during the

reacting process. In another aspect, the reacting may include thermal annealing. In another aspect, the source and drain electrodes may be formed from a member of the group consisting of: platinum silicide, palladium silicide and iridium silicide. In another aspect, the source and drain electrodes may be formed from a member of the group consisting of the rare earth silicides. In another aspect, the insulating layer may be formed from a member of the group consisting of metal oxides. In another aspect, the Schottky contact or Schottky-like region may be formed at least in areas adjacent to the channel. In another aspect, an entire interface between at least one of the source electrode and the drain electrode and the semiconductor substrate may form a Schottky contact or Schottky-like region with the semiconductor substrate. In another aspect, dopants may be introduced into the channel region.

**[016]** In another aspect, the invention provides a device for regulating the flow of electrical current. The device includes a semiconductor substrate, a gate electrode, an electrically insulating layer located between the gate electrode and the semiconductor substrate, the insulating layer having a dielectric constant greater than 4.0, and a source electrode and a drain electrode in contact with the semiconductor substrate and proximal to the gate electrode wherein at least one of the source electrode and the drain electrode forms a Schottky contact or Schottky-like region with the semiconductor substrate. In one aspect, the device for regulating the flow of electrical current may be a Metal Oxide Semiconductor Field Effect Transistor (MOSFET) device. In another aspect, the dielectric constant may be greater than 7.6 or greater than 15.

**[017]** In another aspect, the source and drain electrodes may be formed from a member of the group consisting of: platinum silicide, palladium silicide and iridium silicide. In another aspect, the source and drain electrodes may be formed from a member of the group consisting of the rare earth silicides. In another aspect, the insulating layer may be formed from a member of the metal oxides. In another aspect, the Schottky contact or Schottky-like region may be at

least in areas adjacent to the channel. In another aspect, an entire interface between at least one of the source and the drain electrodes and the semiconductor substrate may form a Schottky contact or Schottky-like region with the semiconductor substrate. In another aspect, the channel region may be doped.

5     **[018]**       Aspects of the invention can include one or more of the following advantages. Conventional field effect transistors (FET) and other current regulating devices require a higher voltage than those fabricated in accordance with the invention to produce a similar drive current from source to drain. In an optimized conventional FET or current regulating device, the drive current varies  
10     generally linearly with the ratio of the insulating layer's dielectric constant to its thickness. One of the advantages of the invention is the unexpected result of the drive current being more sensitive to dielectric constant  $K$  than to  $T_{ins}$ , implying larger drive current  $I_D$  for larger  $K$  and constant  $K/T_{ins}$  ratio. These results are achieved by coupling a Schottky or Schottky-like source and/or drain with an  
15     insulating layer made of a high dielectric constant material. Lower voltage is required to produce high source to drain currents which results in lower power consumption for microelectronics utilizing this architecture.

**[019]**       Furthermore, the well-known benefit of achieving less gate leakage current (between gate and source/drain electrodes) by using larger  $K$  and constant  
20      $K/T_{ins}$  ratio, will still be observed in the present invention. For conventionally architected devices this particular benefit is the sole reason for using materials for the gate insulator having larger dielectric constants  $K$  than that of silicon dioxide, which has a dielectric constant of 3.9. These materials are denoted as "high  $K$ " materials. No other significant benefit is expected or observed. By using  
25     Schottky or Schottky-like source/drain devices in combination with a larger  $K$ , an unexpected and dramatic improvement in drive current  $I_d$  is achieved in addition to the reduction in gate leakage current.

**[020]**       Although there is a strong motivation for the industry to adopt new high  $K$  gate insulator materials due to the problem of gate leakage current, there

are technical obstacles that make production of high K gate insulators challenging. One of the most important problems is the degradation of the high K gate insulator materials during high temperature processing required for the formation of the impurity doped source and drain regions. This degradation is caused by reactions with neighboring materials such as the silicon in the channel region or the gate electrode. The processing steps for the formation of the Schottky or Schottky-like source/drain regions occur at much lower temperatures such as 400 °C as compared to 1000 °C required for impurity doped source and drain formation. As a result of the significantly lower temperature processing steps for the formation of the Schottky or Schottky-like source/drain regions, the high K materials do not react substantially with the neighboring materials. Therefore, another benefit of using Schottky or Schottky-like source/drain devices in combination with high K gate insulator materials is the improved manufacturability of high K gate insulators.

[021] While multiple embodiments are disclosed, still other embodiments of the present invention will become apparent to those skilled in the art from the following detailed description, which shows and describes illustrative embodiments of the invention. As will be realized, the invention is capable of modifications in various obvious aspects, all without departing from the spirit and scope of the present invention. Accordingly, the drawings and detailed description are to be regarded as illustrative in nature and not restrictive.

#### BRIEF DESCRIPTION OF THE DRAWINGS

[022] FIG. 1 is a cross-section of a prior art semiconductor transistor.

[023] FIG. 2 is a cross-section of a semiconductor substrate with Schottky contact source and drain combined with a non-silicon dioxide insulating layer between the gate and channel region.

[024] FIG. 3a is a cross-section of a semiconductor device with Schottky contact source and drain combined with a non-silicon dioxide insulating layer

between the gate and channel region. This is the device structure used for numerical simulations.

[025] FIG. 3b is a logarithmic plot showing the simulated relationship between the drive current  $I_D$  and gate voltage  $V_G$  for various  $K$  values, with the ratio  $K/T_{ins}$  held constant.

[026] FIG. 3c is a linear plot with the same data as FIG. 3b.

[027] FIG. 4a is a cross-section of a semiconductor device with Schottky contact source and drain combined with a non-silicon dioxide insulating layer between the gate and channel region. This is the device structure used for a second set of numerical simulations.

[028] FIG. 4b is a logarithmic plot showing the simulated relationship between the drive current  $I_D$  and gate voltage  $V_G$  for various  $K$  values, with the ratio  $K/T_{ins}$  held constant.

[029] FIG. 4c is a linear plot with the same data as FIG. 4b.

[030] FIG. 5 is a cross-section of semiconductor substrate after ion implantation.

[031] FIG. 6 is a cross-section of semiconductor substrate after insulating layer growth and gate patterning.

[032] FIG. 7 is a cross-section of semiconductor substrate after growth of an oxide layer on the sidewalls.

[033] FIG. 8 is a cross-section of semiconductor substrate after creation of a metal silicide source and drain.

[034] FIG. 9 is a cross-section of the semiconductor device resulting from the process steps outlined in FIG. 10.

[035] FIG. 10 is a flow chart outlining the process flow for the fabrication of a device for regulating flow of electric current in accordance with the invention.

[036] Like reference symbols in the various drawings indicate like elements.

## DETAILED DESCRIPTION

**[037]** Referring to FIG. 2, semiconductor device 200 includes a substrate 210 in which a source 220 and drain 230 are formed. Substrate 210 may be composed of silicon or may be a silicon-on-insulator (SOI) substrate. Source 220 and/or drain 230 may be composed partially or fully of a rare earth silicide. Source 220 and/or drain 230 may also be composed partially or fully of platinum silicide, palladium silicide or iridium silicide. Because the source and drain are composed in part of a metal, they form Schottky contacts or Schottky-like regions 270, 275 with the substrate 210, where a "Schottky contact" is defined by the contact between a metal and a semiconductor, and a "Schottky-like region" is a region formed by the close proximity of a semiconductor and a metal. The Schottky contacts or Schottky-like regions 270, 275 can be formed by forming the source and/or drain from a metal silicide. The Schottky contacts or Schottky-like regions 270, 275 are in an area adjacent to a channel region 240 formed between the source 220 and drain 230. The entire interface between either or both of the source 220 and the drain 230 may form a Schottky contact or Schottky-like region 270, 275 with the substrate 210. The channel region 240 may be impurity doped where the doping may be conventional non-uniform doping or may be uniform doping as described in copending U.S. Patent Application No. 09/465,357 and U.S. Patent Application No. 09/777,536.

**[038]** An insulating layer 250 is formed on top of the channel region 240 and may be formed on part or all of the source 220 and drain 230. The insulating layer 250 is composed of a material with a dielectric constant greater than that of silicon dioxide; e.g. a dielectric constant greater than 3.9. For example, insulating layer 250 may be composed of a metal oxide such as TaO<sub>2</sub> with a dielectric constant of approximately 25, TiO<sub>2</sub> with a dielectric constant of approximately 50-60, HfO<sub>2</sub> with a dielectric constant of approximately 15-20, or ZrO<sub>2</sub> with a dielectric constant of approximately 15-20. The insulating layer 250 may consist of a dielectric with a modest K value (e.g., 5-10), such as nitride/oxide or oxy-

nitride stack; a medium K value (e.g., 10-20), such as unary oxides Ta<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, ZrO<sub>2</sub>, HfO<sub>2</sub>, Y<sub>2</sub>O<sub>3</sub>, La<sub>2</sub>O<sub>3</sub>, Gd<sub>2</sub>O<sub>3</sub>, Sc<sub>2</sub>O<sub>3</sub> or silicates ZrSiO<sub>4</sub>, HfSiO<sub>4</sub>, LaSiO<sub>4</sub>, or TiSiO<sub>4</sub>; or a high K value (e.g., greater than 20) such as amorphous LaAlO<sub>3</sub>, ZrTiO<sub>4</sub>, SnTiO<sub>4</sub>, or SrZrO<sub>4</sub>, or single crystals LaAl<sub>3</sub>O<sub>4</sub>, BaZrO<sub>3</sub>, Y<sub>2</sub>O<sub>3</sub>, La<sub>2</sub>O<sub>3</sub>.  
5 Optionally, to improve manufacturability issues associated with transition metals, the insulating layer 250 may consist of more than one layer. The insulating layer 250 may be formed with a "bi-layer" approach and may consist of more than one type of dielectric, e.g., TiO<sub>2</sub> on top of Si<sub>3</sub>N<sub>4</sub>. A gate electrode 260 is positioned on top of the insulating layer 250. A thin insulating layer 225 surrounds the gate  
10 electrode 260.

**[039]** By forming a semiconductor device with (1) a source 220 or drain 230 forming a Schottky contact or Schottky-like region 270, 275 with the substrate 110; and (2) an insulating layer 250 with a relatively high dielectric constant, one is able to achieve a larger drive current  $I_D$  for larger K, but constant  
15  $K/T_{ins}$ .

**[040]** Referring to FIGs. 3a-c, full two dimensional electrostatic simulations were performed on the MOSFET device 305 structure of FIG. 3a, for various insulating layer 309 thicknesses  $T_{ins}$  307 and insulator dielectric constants K. The simulation assumes the following:

20 **[041]** 1) P type MOS semiconductor device 305, metallic source 301/drain 303 at 300K.

**[042]** 2) Metallic source 301/drain 303 with radius of curvature R 311 of 10nm.

**[043]** 3) Channel length L 313 of 25nm, drain voltage  $V_D$  of 1.2V.

25 **[044]** 4) No significant charge, either fixed or mobile, in the silicon substrate 315.

**[045]** 5) The drain current,  $I_D$ , is limited solely by the emission process at the source 301 end of the semiconductor device 305.

[046]           6)     The current density versus electric field (J vs. E) characteristic for the emission process at the source 301 is modeled after a platinum silicide-to-silicon Schottky contact. The Schottky barrier height is assumed to be 0.187eV, hole effective mass in the silicon is 0.66 $m_0$ , fermi level is at 5.4eV, and temperature is 300K. For a given electric field strength at a particular point on the source 301, the current density is calculated via a complete, no approximations solution to the Schrodinger equation assuming a 1-D sharp triangular barrier. The effects of quantum tunneling and reflection have been fully included. Because the total current density is integrated across the density of states, currents due to field emission, thermal emission, and thermally assisted field emission have been accounted for. The J vs. E relationship has been calibrated to experimental data for the pure thermal emission case ( $E=0$ ).

[047]           These assumptions are valid in the real world case of short channel (<25nm) and undoped (or lightly doped) substrates. Although the absolute values of the calculated source 301 emission currents have not been calibrated for  $E>0$ , they are based on some experimental data and first-principles calculations. For the purposes of the proposed invention, the calculated J vs. E data is sufficient as the primary interest relates to the effect of the insulating layer 309 thickness ( $T_{ins}$ ) 307 and dielectric constant (K) on source 301 emission current. Relative changes in source 301 emission current with  $T_{ins}$  and K are more relevant, in this case, than the absolute value of the current. Nevertheless, calculated values of both leakage and drive currents  $I_D$  are in good agreement with the measured data of actual transistors.

[048]           Simulations were run with a constant  $K/T_{ins}$  ratio of 0.156. The results are shown in FIGs. 3b-c. Starting with FIG. 3c, working upwards, curve 350 shows the relationship between the gate voltage  $V_G$  and the drive current  $I_D$  in a semiconductor device with an insulating layer dielectric constant of 3.9 ( $T_{ins} = 25 \text{ \AA}$ ). Curves 360, 370 and 380 show the ratio of  $V_G$  and  $I_D$  in semiconductor devices with sources 220 and drains 230 that form a Schottky contact or Schottky-

like region 270, 275 with the substrate and insulating dielectric constants of 10 ( $T_{ins} = 64.1 \text{ \AA}$ ), 25 ( $T_{ins} = 160.3 \text{ \AA}$ ), and 50 ( $T_{ins} = 320.5 \text{ \AA}$ ), respectively. Referring to FIG. 3b, curve 355 shows the logarithmic relationship between the gate voltage  $V_G$  and the drive current  $I_D$  in a semiconductor device with an insulating layer dielectric constant of 3.9 ( $T_{ins} = 25 \text{ \AA}$ ). Curves 365, 375 and 385 show the logarithmic ratio of  $V_G$  and  $I_D$  in semiconductor devices with sources 220 and drains 230 that form a Schottky contact or Schottky-like region 270, 275 with the substrate and insulating dielectric constants of 10 ( $T_{ins} = 64.1 \text{ \AA}$ ), 25 ( $T_{ins} = 160.3 \text{ \AA}$ ), and 50 ( $T_{ins} = 320.5 \text{ \AA}$ ), respectively. It is expected that similar results would be achieved regardless of the radius of curvature R 311, channel length 313 and drain voltage  $V_D$ . Drive current to leakage current ratios are 35, 38, 53 and 86 for the curves 350/355, 360/365, 370/375 and 380/385, respectively. Leakage currents can be lowered by at least a factor of 10, without sacrificing drive currents, by the addition of the appropriate dopants in the substrate (to control bulk-punchthrough currents) or by a reduction in operating temperature. Thus, by using a source 301 or drain 303 that forms a Schottky contact or Schottky-like region with the substrate, and by increasing K while maintaining a constant  $K/T_{ins}$  ratio, the drive current  $I_D$  increases significantly (from a little over  $300 \mu\text{A}/\mu\text{m}$  for a  $V_G$  of 1.2V to approximately  $1300 \mu\text{A}/\mu\text{m}$ ). Thus, for a desired drive current, a device would need a significantly lower voltage to operate than that required by the prior art. Because power consumption varies with the square of the voltage, the invention provides for significantly lower power usage.

**[049]** To verify that changing the radius of curvature R 311 does not change the observed dramatic improvement in  $I_D$ , full 2-D electrostatic simulations were repeated on a slightly different device geometry. Referring to FIGs. 4a-c, the semiconductor device 405 structure of figure 4a was simulated for two insulating layer 409 thicknesses  $T_{ins}$  407 and insulator dielectric constants K,

such that the ratio  $K/T_{ins}$  was constant. The simulation assumptions are the same as noted above, with the exception of the device geometry:

[050] 1) The channel length L 413 is 27 nm

[051] 2) The width 402 and height 404 of the source and drain are 100 nm and 30 nm respectively.

[052] 3) The width 412 and height 413 of the gate are 67 nm and 108 nm respectively.

[053] 4) The radius of curvature  $R_g$  414 of the gate was 10 nm for all simulations.

[054] 5) The radius of curvature R 411 of the source and drain electrodes was either 1 nm or 10 nm.

[055] Simulations were run with a constant  $K/T_{ins}$  ratio of 0.205. The results are shown in FIGs. 4b-c. Starting with FIG. 4c, curves 451 and 461 show the relationship between the gate voltage  $V_g$  and the drive current  $I_D$  in a semiconductor device having a radius of curvature R 411 of 10 nm with an insulating layer dielectric constant of 3.9 ( $T_{ins} = 25 \text{ \AA}$ ) and 50 ( $T_{ins} = 244 \text{ \AA}$ ), respectively. Continuing with FIG. 4c, curves 471 and 481 show the relationship between the gate voltage  $V_g$  and the drive current  $I_D$  in a semiconductor device having a radius of curvature R 411 of 1 nm with an insulating layer dielectric constant of 3.9 ( $T_{ins} = 25 \text{ \AA}$ ) and 50 ( $T_{ins} = 244 \text{ \AA}$ ), respectively. Referring to FIG. 4b, curves 455 and 465 show the logarithmic relationship between the gate voltage  $V_g$  and the drive current  $I_D$  in a semiconductor device having a radius of curvature R 411 of 10 nm with an insulating layer dielectric constant of 3.9 ( $T_{ins} = 25 \text{ \AA}$ ) and 50 ( $T_{ins} = 244 \text{ \AA}$ ), respectively. Continuing with FIG. 4b, curves 475 and 485 show the relationship between the gate voltage  $V_g$  and the drive current  $I_D$  in a semiconductor device having a radius of curvature R 411 of 1 nm with an insulating layer dielectric constant of 3.9 ( $T_{ins} = 25 \text{ \AA}$ ) and 50 ( $T_{ins} = 244 \text{ \AA}$ ), respectively. FIGs. 4b-c show that by using a source 401 or drain 403 that forms a Schottky contact or Schottky-like region with the substrate, and by increasing K

while maintaining a constant  $K/T_{ins}$  ratio, the drive current  $I_D$  increases significantly (from approximately 650 mA/mm for a  $V_g$  of 1.2V to approximately 1700 mA/mm) for a device having a radius of curvature  $R_{411}$  of 10 nm. The ratio of drive currents for the  $K=50$  to the  $K=3.9$  case is  $1700/650 = 2.6$ .  
Likewise, for the device having a radius of curvature  $R_{411}$  of 1 nm, the drive current  $I_D$  increases significantly (from approximately 570 mA/mm for a  $V_g$  of 1.2V to approximately 2340 mA/mm). In this case, the ratio of drive current for the  $K=50$  to the  $K=3.9$  case is  $2340/570 = 4.1$ . These results indicate that the relative improvement in drive current  $I_D$  grows larger for smaller radii of curvature  $R_{411}$ . Further, these results indicate that increasing the ratio  $K/T_{ins}$  will lead to larger improvements in drive current  $I_D$  as compared to the case of constant  $K/T_{ins}$ . A conventional impurity doped source and drain device would have approximately the same drive current  $I_D$  for both  $K=3.9$  and  $K=50$  cases having constant  $K/T_{ins}$ .

[056] Cross sectional scanning electron micrographs of the source and drain corner regions indicate that the radius of curvature  $R_{411}$  for the top corner of the source 421 and top corner of the drain 422 electrode adjacent to the channel region are closer to 1 nm, rather than 10 nm. The simulation predictions of FIGs. 4a-c indicate that for a desired drive current, by using a source 401 or drain 403 that forms a Schottky contact or Schottky-like region with the substrate, and by using high  $K$  dielectric gate insulator materials, the device would need a significantly lower voltage to operate than that required by the prior art. Because power consumption varies with the square of the voltage, the invention provides for significantly lower power usage.

[057] The device for regulating flow of electric current described above, for example a planar P-type or N-type MOSFET, may be formed using the process shown in FIGs. 5-9 and described in FIG. 10. (Note that the planar P-type or N-type MOSFET need not be planar in the horizontal direction, but may assume any planar orientation.) Referring to FIGs. 5 and 10, a thin screen oxide

323 is grown on silicon substrate 310, the substrate 310 having a means for electrically isolating transistors from one another (905). The thin screen oxide, optionally a thickness of 200 Å, acts as the implant mask for the channel region 340 doping. The appropriate channel dopant species (for example Arsenic and Indium for P-type and N-type devices respectively) is then ion-implanted through the screen oxide 323 to a pre-determined depth in the silicon (for example, 1000 Å) (910).

**[058]** Referring to FIGs. 6 and 10, the screen oxide layer 323 of FIG. 5 is removed with hydro-fluoric acid (915), and the thin insulating layer 450 is either grown or deposited at least on a portion of the channel region 340 (920). This insulating layer may consist of TiO<sub>2</sub>, TaO<sub>2</sub>, or any other appropriate compound with a high dielectric constant as discussed above. Immediately following the insulating layer growth or deposition, an in-situ heavily doped silicon film is deposited (930). This silicon film will eventually make up the gate electrode. The silicon film may be doped with phosphorus for an N-type device or boron for a P-type device. The gate electrode is then patterned with a lithographic technique and silicon etch that is highly selective to the insulating layer 450 (935).

**[059]** Referring to FIGs. 7 and 10, a thin oxide, optionally approximately 100 Å in thickness, is formed on the top surface and sidewalls of the gate electrode (940). Some of the oxide layers then are removed by anisotropic etch to expose the silicon on the horizontal surfaces 510, while preserving it on the vertical surfaces (945). This step serves both to create a gate sidewall oxide 525 and to electrically activate the dopants in the gate electrode and channel region 340 of the device.

**[060]** Referring to FIGs. 8 and 10, a metal is deposited as a blanket film, optionally approximately 400 Å thick, on all surfaces (950). The particular metal deposited will depend on whether the device is N-type or P-type. Platinum may be used for the P-type device while erbium may be used for an N-type device. The semiconductor device 600 is then annealed for a specified time at a specified

temperature, for example, 45 minutes at 400 °C (955). This temperature is much less the temperature typically required to form impurity doped source and drains, which is usually greater than 800 °C. Where the metal is in direct contact with the silicon, the annealing process causes a chemical reaction that converts the metal to a metal silicide 606. The metal 616 not in contact with silicon does not react.

[061] Referring to FIGs. 9 and 10, the unreacted metal 616 is removed with a wet chemical etch (960). For example, if the deposited metal was platinum or erbium, aqua regia or HNO<sub>3</sub>, respectively, may be used to remove it. The silicide electrodes that remain are the source 620 and drain 630. The Schottky device for regulating flow of electric current with a high dielectric constant insulating layer is now complete and ready for electrical contacting to gate electrode 460, source 620, and drain 630 (965). Because the temperature required to form the Schottky or Schottky-like source and drain electrodes in this process is much lower than that required for impurity doped source 620 and drain 630 regions, the high K material used for the gate insulator 450 is much less likely to react with neighboring materials, making this process much more manufacturable than the prior art.

[062] A number of embodiments of the invention have been described. Nevertheless, it will be understood that various modifications may be made without departing from the spirit and scope of the invention. For example, the semiconductor devices illustrated in the claims are by way of example only. It should be understood that the concepts of the invention apply to semiconductor devices with a variety of cross-sections. And, although the invention has been illustrated with respect to planar silicon MOS transistors, it can apply equally well to other devices for regulating the flow of electrical current. For example, devices built on other semiconductor substrates such as gallium arsenide GaAs, indium phosphide InP, silicon carbide SiC, silicon germanium SiGe, etc. Further, the device is not required to have any particular radius of curvature for the source and

drain electrode corners. And, the invention is not limited to any particular ratio(s) of  $K/T_{ins}$ . Accordingly, other embodiments are within the scope of the following claims.

5      **[063]**      Although the present invention has been described with reference to preferred embodiments, persons skilled in the art will recognize that changes may be made in form and detail without departing from the spirit and scope of the invention.
